TULAREMIA - NORWAY (02): (CENTRAL)

Outbreak of tularemia in central Norway, January to March 2011

From January to March 2011, 39 cases of tularemia were diagnosed in 3 counties in central Norway: 21 cases of oropharyngeal type, 10 cases of glandular/ulceroglandular type, 2 of respiratory, and 2 of typhoid type. 3 cases were asymptomatic and clinical information was unavailable for 1 case. The mean age was 40.3 years (range 2-89 years). 34 reported use of drinking water from private wells. An increased rodent (lemming) population and snow melting may have led to contamination of the wells with infected rodents or rodent excreta.

Outbreak description

From 1 Jan to 25 Mar 2011, 39 confirmed cases (16 female and 23 male) of tularemia were reported from the counties of Sor-Trondelag (28 cases), More og Romsdal (5 cases), and Nord-Trondelag (6 cases) in central Norway. A confirmed case was defined as a person who had clinical symptoms compatible with tularemia or had used drinking water from the same source as a previous case, and in whom _Francisella tularensis_ infection was confirmed by a laboratory test as described below. The cases were geographically scattered within each county, involving 13 different municipalities, and were not linked to one common source. In comparison, 7 cases were reported in total from other parts of the country in the same period. In 2009 and 2010 4 and 8 cases respectively were reported from central Norway.

Tularemia is a zoonotic disease caused by the bacterium _F. tularensis_. 4 _F. tularensis_ subspecies are recognized: _tularensis_, _holarctica_, _mediasiatica_ and _novicida_. In Europe, the infection is due to subspecies _holarctica_, which causes in general less severe disease than subspecies _tularensis_, which is common in North America. Several vectors may be involved in transmitting the disease to humans, commonly rodents and hares, but infection may also be transmitted via insect bites (1).

Several clinical forms are recognised, with oropharyngeal and ulceroglandular disease being the most common clinical presentations in Norway (2). Oropharyngeal disease is commonly associated with contaminated food and water, while ulceroglandular forms are more often seen when there has been skin contact with infected animals or after insect bites (3).

Outbreaks of oropharyngeal tularemia have previously been reported from several European countries (3,4). Tularemia is a notifiable disease in Norway and during the past 10 years, 3 outbreaks were reported in Norway (5-7) and all were associated with water sources in areas where dead lemmings (_Lemmus lemmus_) had been observed previously. From 2001 to 2010, between 3 and 66 cases of tularemia were reported annually in the whole country, with an increase from 16 to 32 cases on average (data available from <http://www.msis.no>). This increase may in part be explained by the outbreaks mentioned above.

Diagnosis and clinical presentation

In the outbreak described here, the most common clinical presentation was fever and pharyngitis (oropharyngeal type, 21 cases) and cervical lymphadenopathy (glandular/ulceroglandular type, 10 cases). Among the remaining 8 tularemia cases, 2 were classified as respiratory and 2 as typhoid type, while 3 were asymptomatic and clinical information was unavailable for 1 case.
The diagnosis was primarily established by serology (microagglutination and an in-house IgG/IgM Elisa) in 30 patients (8), by _F. tularensis_ specific PCR analysis in seven patients (9) and by blood culture (BactAlert, BioMerieux) in 2 patients. The 2 bacterial isolates were verified as _F. tularensis_ by PCR and sequencing of the 16S rDNA gene, and confirmed as non-subspecies _tularensis_ by pdpA PCR (10).

Of the 39 diagnosed cases, 34 had been drinking water from a private well or a stream. _F. tularensis_ DNA was detected by PCR in filtered water from 5 different wells tested in Sor-Trondelag. 7 cases in 1 municipality were linked to the same water source. Apart from that, only 2 cases have been confirmed to share a common well so far.

Follow-up serology has been recommended for several of the persons exposed to some of the putative water sources.

Discussion
----------

The current outbreak involves a large number of municipalities in 3 counties in central Norway. The clinical presentation with oropharyngeal tularemia and cervical lymphadenopathy linked to the use of private wells in the winter season makes contaminated water the most likely source of infection in this outbreak. Detection of _F. tularensis_ DNA by PCR analyses in some of the wells supports this assumption for some of the cases. Use of private wells is relatively common in rural areas of Norway although exact data on such use are not available.

The precise mechanism of contamination of the wells with _F. tularensis_ is as yet unknown. However, November and December 2010 were unusually cold months, while in January 2011 temperatures increased leading to melting of snow and possible contamination of private wells by surface water contaminated with bacteria from rodent cadavers or rodent excreta. Since the incubation period for tularemia may be up to 3 weeks, and time from symptoms until seroconversion might be up to 6 weeks, more cases may follow.

Tularemia has traditionally been called both 'lemming fever' and 'hare plague' and this clearly indicates rodents and hares as transmitters of disease. Years with a great increase in the rodent population are seen with intervals of about 3 to 4 years (11) and in the summer and autumn of 2010, a high density of lemmings could be observed in the southern and central parts of Norway. Simultaneously, the Norwegian Veterinary Institute observed a wide geographical distribution of fatal cases of tularemia in the mountain hare (_Lepus timidus_) in these regions (12). The mountain hare is very susceptible to this infection and normally dies from septicemia within a few days after exposure.

The use of small streams and private wells as a source of drinking water and for other purposes in rural areas of Norway is a matter of concern. In existing guidelines issued by the National Institute of Public Health the population is advised to boil drinking water and inspect the wells for dead rodents in case of suspected or confirmed cases of waterborne tularemia. Every well owner should make the necessary effort to prevent small rodents from entering the well water by carefully covering every opening and plugging every small hole where the rodents can enter. It is also important to secure the well from contamination by surface water after snow melting. In case of proven or suspected contaminated wells, the water should be disinfected before further use. However, this may not be feasible for persons who use drinking water from a stream. The Norwegian Food Safety Authority has recently released information to the media and to the general public with similar advice and information in relation to the current outbreak. The local health authority in each municipality is responsible for instituting infection control measures including advice to the public and investigations of the putative drinking water sources.

[Regarding water-related outbreaks of tularemia, outbreaks include 64 cases in Dagestan, Russia associated with a flood-plain swamp (1), 49 cases in Tuscany, Italy linked to an unchlorinated water system (2), and an outbreak in the Smolensk province of Russia also attributed to contamination of a water supply (3).
